(Received 4 January 2011; accepted 15 February 2011; published online 7 March 2011)

The structural stability of the ternary alloy  $Mo(Si_{1-x}, Al_x)_2$  with different *x* has been investigated using first-principles pseudopotential plane wave method. The electronic origin of the  $C11<sub>b</sub>$  $\rightarrow$  *C*40 phase transition is revealed by analyzing the density of states and *d*-band splitting induced by the crystal field. We further propose the feasibility of controlling the microscopic structure by adding a quaternary component according to the mechanism presented in this work. © *2011 American Institute of Physics*. doi[:10.1063/1.3562593](http://dx.doi.org/10.1063/1.3562593)

In recent years,  $MoSi<sub>2</sub>$  has attracted much attention as a potential candidate for high-temperature materials because of its excellent properties, such as high melting point (2293 K), low density, and oxidation resistance. The most severe impediment for the structural application of  $M_0Si_2$  is the pest disintegration around 780 K.<sup>1,2</sup> Many experiments<sup>3-8</sup> have shown that alloying with Al can significantly improve the resistivity of  $MoSi<sub>2</sub>$  toward the pest disintegration. Al substitution can also improve the structural toughness at lowtemperatures, making  $Mo(Si_{1-x}, Al_x)_2$  a suitable alloy for turbine blades or coating. Recently, Pankhurst *et al.*<sup>9</sup> observed that when the concentration of Al in  $Mo(Si_{1-x}, Al_x)_2$  is beyond 10 at. %, the crystal structure transforms from the  $C11<sub>b</sub>$ to the *C*40 structure. Several other works also reported the effects of ternary and quaternary addition on controlling the structure of  $\text{MoSi}_2$ .<sup>10–13</sup> Despite extensive experimental efforts, an in-depth understanding of the mechanism driving the structural transition is still lacking. In the present work, we reveal the microscopic mechanism of the phase transition in  $MoSi<sub>2</sub>$  due to Al-doping using first-principles calculations.

The first-principles calculations were carried out using VASP package<sup>14</sup> with Perdew and Wang<sup>15</sup> exchange correlation functional and an energy cutoff of 350 eV. To compare the stability of both structures of  $Mo(Si_{1-x}, Al_x)_2$  with different *x*, a  $3 \times 1 \times 1$  supercell of  $C11_b$  and a  $2 \times 1 \times 1$  supercell of C40 were employed (shown in Fig. 1). Three Al concentrations,  $x=0$ , 8.3, and 16.7 at. %, were considered. In the case of  $x=16.7$  at. %, we have considered all the configurations in which two Al atoms substitute different Si sites, and the configuration with the lowest energy is taken as the ground-state. A  $5 \times 10 \times 7$  *k*- mesh is adopted following the Monkhorst–Pack scheme.<sup>16</sup> The whole structure was allowed to relax until the force on each atom is less than 0.02 eV/Å. Our convergence test showed that the total energies is better than 1 meV/atom.

We begin our discussion by noting the rules for site occupancy of Al in two phases with  $x=16.7$  at. %. Two

quantities are taken to characterize the dopant distribution: the nearest distance between the two Al atoms, and the number of Al–Al pairs with distance shorter than a given  $R_{cut}$ (=4.5 Å), which is slightly larger than the third nearest neighbor Al–Al distance in  $C11<sub>b</sub>$  and the fifth nearest neighbor Al–Al distance in *C*40, respectively. The results are listed in Table I. In the  $C11<sub>b</sub>$  case, the structure prefers longer "nearest distance" and fewer "number of Al–Al pairs," which indicates a uniformly and sparse distribution of Al in  $MoSi<sub>2</sub>$ . In contrast, there is no clear trend for favorable site occupancy of Al in *C*40 structure. Generally speaking, the average distance between the Al–Al pair is smaller in *C*40 than that in  $C11_h$ .

The lattice constant of each structure expands with the increasing *x* due to the larger radius of Al atoms compared to Si atoms. *pV* term is, however, ignored since the relative difference of volumes of supercells of  $C11<sub>b</sub>$  and  $C40$  structures is smaller than 0.6% with the same *x*. Further, *C*40 was observed to be the ground state due to the Al substitution at room temperature.<sup>9</sup> And the difference of vibrational free energies between *C*40 and  $C11_b \Delta F_{\text{vib}}^{C40-C11_b}$  is estimated as 26 meV at 300 K in the present work. These two facts suggest ignoring vibrational entropy will not change our conclusions. We thus focus on the total energy  $(E)$  for the rest of the paper. Figure 2 shows the total energy curves of two structures with different *x*.  $E_{C11_b}$  and  $E_{C40}$  both rise with increasing substitution of Al, and the effect on  $C11<sub>b</sub>$  structure is

FIG. 1.  $3 \times 1 \times 1$  *C*11<sub>*b*</sub> supercell (left) and  $2 \times 1 \times 1$  *C*40 supercell (right). Dark large circles and light small circles represent Mo and Si atoms, respectively. Dark small circles indicate the lowest-energy positions for Al substitution. Lattice sites are marked by Arabic numerals 1–12.

TABLE I. The total energies with different occupation position of Al. The abbreviation "Num" means "the number of Al–Al pairs with distance shorter than  $R_{\text{cut}}$ " and "Dis" means "the nearest distance of Al–Al pair," respectively. In each case, the ground energy is set as zero.

(a) $C11_h$ case							
Al-occupying site	Dis $(\AA)$	Num	$E_{tot}$ (meV)				
1, 10	2.616	3	125				
1, 4	2.616	$\overline{2}$	57				
1, 2	3.204	1	43				
1, 7	4.531	$\theta$	37				
2, 4	5.231	$\overline{0}$	$\overline{0}$				
(b) $C40$ case							
1, 6	2.566	$\overline{2}$	125				
1, 9	2.566	1	121				
1, 2	2.686	1	51				
1, 5	3.219	1	43				
1, 8	2.622	2	26				
1, 10	4.565	$\theta$	19				
1, 11	3.166	1	$\overline{0}$				

more substantial. In the case of  $x=0$  at. %,  $C11<sub>b</sub>$  phase has the lower energy, and thus is the ground state of  $MoSi<sub>2</sub>$ . With  $x=8.3$  at. %, the two curves become almost isoenergetic, and we can expect the coexistence of two phases. When the concentration of Al increases to 16.7 at.  $\%$ ,  $E_{C40}$  becomes lower than  $E_{C11_b}$  by 368 meV. Correspondingly, the groundstate structure of  $Mo(Si_{1-x}, Al_x)_2$  changes from  $C11_b$  to  $C40$ . Thus we demonstrate the phase transition of  $Mo(Si_{1-x}, Al_x)_2)$ occurs when *x* goes from  $\sim$ 8.3 to  $\sim$ 16.7 at. %, which agrees with the experimental observation.<sup>9</sup>

Using of Murnaghan equation, the bulk modulus  $(B_0)$ 's of the two phases with different *x* are obtained and listed in Table II.  $B_0$ 's of both phases decrease with the increase in the Al concentration. This can be attributed to the weaker chemical bonding of Al compared with Si. Also it has been sug-

FIG. 2. (Color online)  $E$  vs  $V$  with different  $x$ : (a) 0 at. %, (b) 8.3 at. %, and (c) 16.7 at. %. The black circle and red (gray) square represent  $E_{C11_b}$  and  $E_{C40}$ , respectively. *V*<sub>0</sub> is the equilibrium volume of Mo(Si<sub>1−*x*</sub>, Al<sub>*x*</sub>)<sub>2</sub>.  $E_{C11}$ <sub>*b*</sub> of This an MoSizis set to zero as indicated in the article. Reuse of AIP content is subjected use the real is set to zero and represented by the vertical bue nloaded to IP:

TABLE II. The bulk modulus  $B_0$  (Mbar) of  $C11_b$  and  $C40$  with different *x*. The optical phonon frequencies  $\nu$ (cm<sup>-1</sup>) of  $C11<sub>b</sub>$  structure. Values in parenthesis are from Ref. 18.

	$\mathcal{X}$ $(at, \%)$	$\overline{0}$	8.3	16.7
$B_0$ (Mbar)	$C11_h$	2.07	2.03	2.02
	C40	2.02	1.99	1.95
$\nu$ (cm <sup>-1</sup> )	$E_{g}$	440 (440)	437	426
			429	422
	$A_{1g}$	322 (325)	314	304

gested that phonon modes might lead to phase transitions.<sup>17</sup> We thus calculated  $A_{1g}$  and  $E_g$  phonon frequencies of  $C11_b$ structure to understand the mechanism behind this  $C11<sub>b</sub>$  $\rightarrow$  *C*40 transition (shown in Table II). The substitution of Al softens both phonon modes and lifts the degeneration of  $E_{\varrho}$ mode. Furthermore, there is no imaginary frequency with *x* =16.7 at. %. Thus the  $C11<sub>b</sub>$  is still a metastable structure for  $Mo(Si<sub>1-x</sub>, Al<sub>x</sub>)<sub>2</sub>$  with high *x* values. This result indicates that phonon modes are not dominant factors in the dopinginduced phase transition. This also drives us to investigate the origin of the phase transition on electronic structure rather than phonon modes.

Figure 3 shows the density of states (DOS) of  $C11<sub>b</sub>$  and *C*40. The Fermi energies  $(E_F$ 's) of both structures shift downwards with the increase in *x*. The effect of Al on the electronic structure transforms MoSi<sub>2</sub> with *C*40 structure from semiconductor to metal [Fig.  $3(b)$ ]. Near  $E_F$ , the DOS of both structures are mainly composed of *d*-bands but with different *d*-bands splitting. Such differences can be attributed to the different symmetries of these two phases. Based on the crystal field theory, the symmetry of  $MoSi<sub>2</sub>$  with  $C11<sub>b</sub>$  structure is  $D_{4h}$ , the *d*-bands reduces to  $A_{1g} \oplus B_{1g} \oplus B_{2g} \oplus E_g$ , and  $E_g$  subband lies nearest to the  $E_F$ . The symmetry of C40 structure is  $D_6^4$ , the *d*-bands reduces to  $A_1 \oplus E_a \oplus E_b$ , and  $A_1$  is the subband which is nearest to the  $E_F$ . One should note that strictly speaking, the symmetry of system is broken due to the substitution of Al to Si, but as shown in Fig. 3, the profiles of DOS are similar and insensitive to *x*. Thus the analy-

FIG. 3. DOS of  $C11<sub>b</sub>$  (a) and  $C40$  (b) structure, respectively. From bottom to top, DOS of  $x=0$  at. %, 8.3 at. %, and 16.7 at. %, respectively. The peaks of reduced subbands are indicated by arrows for both structures. Insets are the enlargement of the DOS near the  $E_F$  of both structures for  $x$ 

sis on the symmetry still approximately holds.

Several studies have related the relative structural stability of alloys to DOS by, for example, the pseudogap effect<sup>19,20</sup> or the Jones-type analysis.<sup>9,21–23</sup> As an extension of previous models, we propose here a set of phenomenological criteria for predicting the structural stability using DOS. Namely, the system stability decreases as follows: (i)  $n'(E_F)=0; n''(E_F) > 0$ , (ii)  $n'(E_F) < 0$ , (iii)  $n'(E_F) > 0$ , and (iv)  $n'(E_F)=0; n''(E_F)<0$ . where  $n'(E_F)$ ,  $n''(E_F)$  represent  $(\partial n(E)/\partial E)|_{E_F}$  and  $(\partial^2 n(E)/\partial E^2)|_{E_F}$ , respectively. As shown in Fig. 3, when *x* is 8.3 at. %,  $n'(E_F)$  of  $C11_b$  and  $C40$  are both negative and almost equal, thus energy difference is small and  $Mo(Si_{1-x}, Al_x)_2$  can be expected to have multiphases.<sup>9</sup> When  $\bar{x}$ =16.7 at. %, the  $E_F$  of *C*40 structure lies at the local minimum between the  $A_1$  and  $E_b$  subbands  $[n''(E_F) > 0]$ . On the other hand, the  $E_F$  of  $C11_b$  structure just lies at the local maximum of  $E_g$  subband,  $[n''(E_F) < 0]$ . Thus *C*40 phase is more stable, and the ground-state structure of  $Mo(Si<sub>1-x</sub>, Al<sub>x</sub>)<sub>2</sub>$  changes from  $C11<sub>b</sub>$  to  $C40$ . We thus reveal here the electronic origin that drives the phase transition: because of the different crystal field symmetry, *d*-bands of  $C11<sub>b</sub>$  and *C*40 structures reduce to different subbands. There are two subbands,  $A_1$  and  $E_b$ , just below the  $E_F$  for C40 structure. Thus, DOS of *C*40 has a local minimum nearer to the  $E_F$  compared with that of  $C11<sub>b</sub>$ . The substitution of Al 16.7 at. % changes the position of the  $E_F$  according to rigid band model, places the  $E_F$  of  $C40$  at this minimum, and drives the observed phase transition.

These criteria are expected to be more general and can be used to guide the design of high-order MoSi<sub>2</sub>-based alloy. We propose the ground-state structure control of  $Mo(Si<sub>1-x</sub>, Al<sub>x</sub>)<sub>2</sub>$  by alloying with other transition metal elements, for example, to keep the  $C11<sub>b</sub>$  with high concentrations of Al by alloying with  $VII_B$  group elements, or to accelerate the phase transition at lower *x* by alloying with  $V_B$ group elements. To demonstrate the above prediction, We build four-order alloys by substituting Re and Nb to one of the Mo atoms in supercells of both  $C11<sub>b</sub>$  and  $C40$ , respectively. Due to the substitution of Nb, *C*11*b*, and *C*40 co-exist in the alloy without Al, and in the case of  $x=8.3$  at. %,  $C40$ is already the ground state  $(E_{C40} \text{ is } 190 \text{ meV lower})$ . In contrast, alloying Re keeps  $C11<sub>b</sub>$  as the ground state till *x*  $= 16.7$  at. %  $(E_{C11_b}$  is favored by 114 meV). According to the electronic mechanism presented above, because the number of valence electrons of Nb is less than that of Mo, the  $E_F$ of  $C$ 40 will shift to the local minimum between the  $A_1$  and

 $E_b$  subbands at relative lower *x*, and accelerate the phase transition. In the case of  $(Mo, Re)$   $(Si<sub>1-x</sub>, Al<sub>x</sub>)<sub>2</sub>$ , the trend is opposite.

In conclusion, we investigated the detailed mechanism of the phase transition in  $Mo(Si<sub>1-x</sub>, Al<sub>x</sub>)<sub>2</sub>$  using firstprinciples calculations. Based on the DOS and crystal field symmetry analysis, it was found that the phase transition is largely determined by the position of the Fermi level with respect to the local maximum of the subbands. We further demonstrate the feasibility of controlling the desired microscopic structure of  $Mo(Si_{1-x}, Al_x)_2$  by adding a quaternary component.
